Enhanced microfluidic mixing via a tricritical spiral vortex instability

S.J. Haward, R.J. Poole, M.A. Alves, P.J. Oliveira, N. Goldenfeld, and A.Q. Shen,

Experimental measurements and numerical simulations are made on fluid flow through cross-slot devices with a range of aspect (depth:width) ratios, $0.4 < \alpha < 3.87$. For low Reynolds numbers $Re$, the flow is symmetric and a sharp boundary exists between fluid streams entering the cross-slot from opposite directions. Above an $\alpha$-dependent critical value $20 < Re_c(\alpha) < 100$, the flow undergoes a symmetry-breaking bifurcation (though remains steady and laminar) and a spiral vortex structure develops about the central axis of the outflow channel. An order parameter characterizing the instability grows according to a sixth-order Landau potential, and shows a progression from second order to first order transitions as $\alpha$ increases. A tricritical point occurs for $\alpha \sim 0.55$. The spiral vortex acts as a mixing region in the flow field and this phenomenon can be used to drive enhanced mixing in microfluidic devices.

(a) Schematic diagram of a cross-slot device. Fluorescently-dyed fluid enters from positive $y$ and undyed fluid enters from negative $y$. Flow exits along the $x$-direction. Confocal microscopy is performed in $z$-planes, which are scanned through the full depth of the device and used to reconstruct images in the $x = 0$ plane (green shaded region).

(b) Three-dimensional (3D) rendering of a vortex structure observed for the flow of water at $Re = 75.8$ in a cross-slot with $\alpha = 1$. The image is generated from $z$-plane images spaced at $\delta z = 5 \ \mu m$ and has been cropped around the central vortex. The volume shown corresponds to the fluorescently-dyed fluid stream.

Development of the spiral vortex structure in the $x = 0$ plane as the Reynolds number ($Re$) is varied: (a) $Re = 15.2$, (b) $Re = 42.8$, (c) $Re = 60.6$, (d) $Re = 91.0$. Scale bar in (a) represents 200 $\mu m$.
